1. Project Overview

CallHub is a web-based institutional directory and contact management system built for a university setting. It allows different kinds of users - directors, faculty, staff, students, and wardens- to log in and view or manage member profiles, contact details, locations, and emergency contacts. Each user sees only the information they are allowed to see, based on a role-based access control (RBAC) system tied to data categories.

This report covers Module B of the assignment, which focuses on how the system behaves when many users interact with it simultaneously. The goal is to verify that the system remains correct, safe, and responsive even under heavy concurrent load, during conflicting writes, and after failures.

The system was tested using four custom Python scripts. Each script runs a different kind of experiment, saves a JSON report to the benchmarks/ folder, and prints a clear PASS or FAIL verdict to the terminal. The four experiments are:

- Concurrent Usage Test — multi_user_test.py
- Race Condition and Failure Simulation — race_failure_test.py
- Stress Test — stress_test.py and locustfile.py

2. System Architecture

The backend is a Python Flask application that connects to a MySQL database. All write operations (create, update, delete) are performed within MySQL transactions with autocommit disabled, so every multi-step operation either commits fully or rolls back completely. JWT-based authentication ensures that each request carries the user's identity and role securely.

The database enforces referential integrity using foreign keys. For example, if a new member is being created and the second INSERT into Contact_Details fails, the entire transaction is rolled back, leaving no partially created member in the database. This is the core of what the tests below verify.

3. What We Tested and Why

The assignment asks us to verify four key database properties under real-world multi-user conditions. These are known as the ACID properties:

Atomicity	Every operation either completes fully or not at all. If something goes wrong halfway through, the database reverts to its previous state.
Consistency	The data always follows all the rules — no missing foreign keys, no corrupted records, no invalid states.
Isolation	One user's actions do not interfere with another's. An unauthorized user cannot modify data they do not own.
Durability	Once a transaction is committed, the data stays saved — even if the application crashes right after.

4. Implementation 1: Concurrent Usage Test

4.1 What This Test Does

The concurrent usage test is run by multi_user_test.py. It simulates multiple users doing things at the same time — specifically, logging in and reading their own profile data, and in the second part, multiple admin users updating the same member record simultaneously.

The script uses Python's ThreadPoolExecutor to run many requests in parallel, just like real users would. Each thread logs in, gets a JWT token, and then does its operation. Results are collected and analyzed together.

4.2 How the Script Works

The script's core logic is straightforward. It creates a pool of worker threads, assigns each thread a user and an operation, and collects the results:

```python
    with ThreadPoolExecutor(max_workers=self.workers) as pool:
        for i in range(total_requests):
            user = self.users[i % len(self.users)]
            futures.append(
                pool.submit(
                    self._run_single,
                    user,
                    mode,
                    i,
                    create_category_name,
                    create_role_title,
                    delete_member_id,
                )
            )

        for future in as_completed(futures):
            try:
                records.extend(future.result())
            except Exception as exc:
                records.append({"operation": "internal", "ok": False, "error": str(exc)})
```

Each _run_single call logs in with fresh credentials, then either reads the user's own profile or attempts an admin update. Second, concurrent shared updates — the script filters down to only admin accounts and fires 100 update requests on the same target member in parallel. In our dataset, the only admin in the test_users file is Prof. Arvind Mishra, so all 100 updates are logged under his session.

We checked this part by sending concurrent read and update requests only.

The admin update scenario first fetches the current member data, modifies the name field, and then PUTs the updated record back:

```python
def _new_session(self) -> requests.Session:
    session = requests.Session()
    session.headers.update({"Content-Type": "application/json"})
    return session

def _admin_users(self) -> list[dict]:
    admins = []
    for user in self.users:
        session = self._new_session()
        ok, _ = self._login(session, user["username"], user["password"])
        if not ok:
            continue
        try:
            res = session.get(f"{self.base_url}/check-admin", timeout=10)
            if bool(res.json().get("is_admin")):
                admins.append(user)
        except Exception:
            pass
    return admins

def _login(self, session: requests.Session, username: str, password: str) -> tuple[bool, dict]:
    t0 = time.perf_counter()
    try:
        response = session.post(
            f"{self.base_url}/login",
            json={"username": username, "password": password},
            timeout=15,
```

4.3 Test Configuration

The test was run with the following parameters:

```
python multi_user_test.py --read-requests 10 --workers 10 --include-records
```

The arguments: --read-requests 10 sends 10 parallel reads, --workers 10 caps the thread pool at 10, and --include-records just adds detailed per-request data to the saved JSON output—it doesn't trigger the updates; those run by default.

Three users were used: Prof. Arvind Mishra (Admin), Mrs. Geeta Ben (Warden), and Riya Sen (Student). The system ran 10 concurrent reads and 100 concurrent shared updates using the admin user pool.

callhub_backend > {} test_users.json > ...

```
[
  {
    "username": "Prof. Arvind Mishra",
    "password": "arvind"
  },
  {
    "username": "Riya Sen",
    "password": "riya"
  },
  {
    "username": "Mrs. Geeta Ben",
    "password": "geeta"
  }
]
```

4.4 Results and Explanation

Following is the output of multi_user_test.py

```
(venv) PS C:\Users\arpit\OneDrive\Desktop\CallHub-CS-432\Datadynamics_Assignment3_Track1\Module_B\callhub_backend> python multi_user_test.py --target-member-id 1 --include-r
ecords
Concurrent usage test complete

        "min": 31.313,
        "avg": 35.639,
        "p95": 40.352,
        "max": 44.488
      }
    },
```

100 concurrent update operations by admin users, all targeting the same member record. Every update succeeded—the database handled them cleanly, one after the other, without corruption.

After all 100 updates, the final state of the record was read back and found to be valid — the member data was not corrupted. The RBAC system correctly returned full profile data (contacts, emergency contacts, locations) for the admin user.

```
        "operation": "update",
        "actor": "Prof. Arvind Mishra",
        "status_code": 200,
        "ok": true,
        "time_ms": 70.64899997203611,
        "response": {
          "message": "Member updated"
        },
        "payload_tag": "Prof. Arvind Mishra_10_8866"
      },
```

What this proves: Multiple users reading and writing at the same time did not corrupt data or cause users to interfere with each other. The final member state was valid after all 100 concurrent writes, which directly demonstrates **Consistency** and basic **Isolation**.

Complete JSON output can be seen here:
[Datadynamics_Assignment3_Track1/Module_B/benchmarks/concurrent_usage_report.json]

5. Implementation 2: Race Condition and Failure Simulation

5.1 What This Test Does

The race condition and failure simulation test is run by race_failure_test.py. It has two parts. The first part is a race test: many admin threads simultaneously try to update the same member's name, and we verify that the result is always legitimate (the final name is the one actually submitted — not some corrupted in-between value). The second part is a failure simulation: we intentionally cause a transaction to fail and verify that the database rolls back properly, leaving no partial data behind.

5.2 How the Race Test Works

60 concurrent update attempts are fired at the same member (member_id=1). Each attempt generates a unique name tag so we know exactly which thread's write won. After all threads finish, we read the member back and confirm the final name matches one of the names that were successfully written:

```
final_name = final["data"].get("full_name") if isinstance(final.get("data"), dict) else None
successful_update_count = len(successful_names)
```

```
        "correctness": {
            "all_attempts_accounted_for": len(results) == attempts,
            "no_5xx": all(int(r.get("status") or 0) < 500 for r in results),
            "last_write_wins_legitimate": final_name in successful_names if final_name else False,
            "successful_update_count": successful_update_count,
        },
```

The key check is last_write_wins_legitimate — the final state of the database must be one of the values that was actually submitted by a successful concurrent write. This rules out data corruption or random values.

5.3 How the Failure Simulation Works

The failure simulation creates a new member with a specific username (the 'seed') and then immediately attempts to create another member with the same username, which violates the unique constraint and causes a 500 error. We then check that the failed create did not leave any member row in the database with the bad name:

```
    good_payload = build_create_payload(tag, dup_username, good_password, category_name, role_title, good_name)

    # Step 1: successful create (seed)
    c1_status, c1_data = create_member(admin_session, good_payload)
    seed_member_id = c1_data.get("member_id") if isinstance(c1_data, dict) else None

    # Step 2: forced failure create using same username (unique violation expected)
    bad_name = f"FailureShouldRollback_{tag}"
    bad_payload = build_create_payload(tag, dup_username, "AnotherPass123!", category_name, role_title, bad_name)
    c2_status, c2_data = create_member(admin_session, bad_payload)

    # Step 3: verify rollback/no partial member row with failed full_name
    lm_status, lm_data = list_members(admin_session)
    failed_name_exists = False
    if lm_status == 200 and isinstance(lm_data, list):
        failed_name_exists = any(str(m.get("full_name")) == bad_name for m in lm_data)
```

5.4 Results and Explanation

```

Output saved in the JSON file

Complete JSON output can be seen here:
[Datadynamics_Assignment3_Track1/Module_B/benchmarks/race_failure_report.json]

What this proves: Under race conditions, the database never ends up with a corrupted or random value — it always reflects one of the legitimate concurrent writes. When a transaction fails midway, MySQL rolls it back completely — no partially created members are stored. This directly demonstrates **Atomicity** (rollback) and **Consistency** (no corrupt state after concurrent writes). After the 500 error/failure was triggered, the previously successful data (the "seed") was still present and uncorrupted in the database, this shows **Durability.**

6. Implementation 3: Stress Test

6.1 What This Test Does

We have generated an additional 200 fake members using the seed_more_members.py file for stress testing. The stress test is implemented in locustfile.py using Locust. The script stress_test.py is a small headless launcher that converts command-line arguments into Locust runtime settings, starts the load generator, and saves the final summary JSON to benchmarks/locust_stress_summary.json. This keeps all load-generation logic in one place and makes results easy to reproduce.

The Locust workload covers three behaviours in every virtual user. Each user logs in using credentials from test_users.json, then checks whether they are an admin via /check-admin. Admin users then repeatedly read and update the shared target member, while non-admin users read their own profile and occasionally attempt a forbidden update to verify access control. This means the test simultaneously exercises load, concurrency, authorization enforcement, and update behaviour.

The command used to run it was:

```
python stress_test.py --target-member-id 1 --requests 1000 --workers 50
                      --update-every 4 --unauth-update-every 10
```

6.2 How the Locust Workload Works

In locustfile.py, each Locust virtual user selects a real test account from test_users.json, logs in once at startup, and stores whether the account is an admin.

It then runs a weighted task loop:

- admin users mostly read the shared target member and occasionally update the member’s name, while regular users mostly read their own profile and occasionally attempt an unauthorized update.
- Metrics are collected continuously and written to locust_stress_summary.json at the end of the run.

```python
        creds = random.choice(load_users())
        self.username = creds["username"]
        self.password = creds["password"]

        login_response = self.client.post(
            "/login",
            json={"username": self.username, "password": self.password},
            name="POST /login",
        )
        if login_response.status_code != 200:
            with _lock:
                _metrics["login_fail"] += 1
            return

        with _lock:
            _metrics["login_ok"] += 1

        login_data = safe_json(login_response)
        self.member_id = login_data.get("member_id")

        admin_response = self.client.get("/check-admin", name="GET /check-admin")
        if admin_response.status_code == 200:
            self.is_admin = bool(safe_json(admin_response).get("is_admin"))
```

```python
def _unauthorized_update(self) -> None:
    if self.member_id is None:
        return

    payload = {
        "full_name": f"Unauthorized_{self.member_id}_{random.randint(1000, 9999)}",
    }

    with self.client.put(
        f"/members/{TARGET_MEMBER_ID}",
        json=payload,
        name="PUT /members/:id (unauthorized)",
        catch_response=True,
    ) as response:
        if response.status_code == 403:
            with _lock:
                _metrics["unauth_update_denied"] += 1
            response.success()
        else:
            with _lock:
                _metrics["unauth_update_other"] += 1
                if self._infra_status(response.status_code):
                    _metrics["infra_errors"] += 1
            response.failure(f"expected 403, got {response.status_code}")
```

6.3 Understanding the Console Output

The repeated tables in the console are normal — they are live progress snapshots that Locust prints every few seconds during the 30-second run. The most important line is the final aggregated row, which summarises the entire run. Each endpoint shown in the output corresponds to a distinct part of the test:

- **POST /login** records authentication performance
- **GET /check-admin** confirms role detection
- **GET /members/:id (admin),** and **PUT /members/:id (admin)** measure authorized reads and updates
- **PUT /members/:id (unauthorized)** verifies that regular users are blocked with 403, which is treated as a pass
- **GET /members/:id (self)** shows that regular users can still read their own records even when the system is under load.

6.4 Key Code — How Operations Are Mixed

The stress test decides what each request does based on its index number, so reads, updates, and unauthorized attempts are spread evenly across the 1,000 total requests:

```python
def task(i: int) -> dict:
    actor = admin_users[i % len(admin_users)]
    s = new_session(base_url)
    ok, login_info = login(s, actor["username"], actor["password"])
    if not ok:
        return {"i": i, "op": "login", "ok": False, "status": login_info["status"], "details": login_info}

    new_name = f"RaceUpdate_{i}_{now_tag()}"
    t0 = time.perf_counter()

Load Test Result - 50 workers

Total Requests	3,598
Total Failures	**0 / 3,598**
Failed Requests	0
Throughput	**126.08 requests per second**
No HTTP 500 errors in load	**true**

The **--requests 1000** argument passed to **stress_test.py** is not a hard request cap — it is used only to calculate how long the test should run. Internally, the script computes the runtime as

max(30, ceil(1000 / 50)) = 30 seconds, so Locust runs for a fixed 30-second window regardless of the number of requests.

During that 30-second window, Locust counts every single HTTP call made across all 50 virtual users. This includes the initial login call per user, the `/check-admin` role-detection call, prefetch GET requests that admin users make before each update, admin reads and updates on the shared member, unauthorized PUT attempts by non-admin users, and self-read traffic from regular users throughout the run. All of these are summed together in the final Locust statistics, which is why the reported total reaches 3,598 even though the input was 1,000.

The exact count also varies across runs due to random user selection, random read-vs-update decisions, variable wait times between tasks, and differences in concurrent scheduling. This is expected and correct behaviour for a time-based load test — the `--requests` flag controls duration, not a strict ceiling on the number of HTTP calls.

ACID Verification Results

Atomicity — rollback verified	**true**
Consistency — final name from valid updates	**true**
Isolation — unauthorized updates denied	**218 / 218 blocked (all 403)**
Durability — data persisted after a delay	**true — data stable across reads after run**

Complete JSON file can be seen here:
[Datadynamics_Assignment3_Track1/Module_B/benchmarks/locust_stress_summary.json]

What this proves: The system handled 3,598 requests at 126+ req/s over a 30-second run without a single failure. All 50 simulated users authenticated successfully, every admin update succeeded, and every unauthorized update attempt was correctly blocked with an HTTP 403 response.

The median response time remained at 23 ms, and the 95th percentile reached 90 ms, which is well within acceptable bounds. This confirms the system is stable, correctly authorized, and responsive under sustained concurrent load. All 218 unauthorized update attempts were **denied** — the RBAC system held up under load.

No unexpected server errors occurred, no logins failed, and no authorization bypasses were observed. The JSON summary in benchmarks/locust_stress_summary.json is the key reference for the report, providing a clean, machine-readable record of the complete run. This directly demonstrates **Isolation** (no authorization bypasses) and **Consistency** (no 5xx errors, no data

corruption) under sustained concurrent load, and **Durability** (indirectly) as the previous data persisted.

7. How Correctness, Failures, and Conflicts Are Handled

7.1 How Correctness Is Ensured

The system ensures correctness and data consistency through a multi-layered approach involving transaction management, database constraints, role-based access control (RBAC), and index synchronization

The system relies on MySQL constraints such as foreign keys, unique constraints, and data type validations to enforce data integrity. Even if invalid or inconsistent data is sent from the application layer, the database rejects such operations. This rejection triggers an exception that rolls back the transaction, thereby preserving the correctness of the stored data.

Before any request reaches the database layer, the system performs RBAC authorization checks. This ensures that users can only access or modify data they are permitted to handle. Unauthorized requests are immediately rejected with an HTTP 403 status code, preventing any unintended or malicious database operations.

7.2 How Failures Are Handled

All database operations are wrapped in try/except blocks. When an IntegrityError (e.g., a duplicate username or a bad foreign key) or any other database error is caught, the code immediately calls conn.rollback() and returns an appropriate HTTP error response. The caller gets a clean error message, and the database is exactly as it was before the failed request.

7.3 How Multi-User Conflicts Are Handled

The system uses a last-write-wins approach for concurrent updates, which is appropriate for this assignment level. When two admin users update the same member at the same time, MySQL's row-level locking ensures that each UPDATE runs atomically — one after the other, not simultaneously. The final state is always exactly one of the submitted values, never a corrupted blend of two.

For read operations, MySQL's default REPEATABLE READ isolation level ensures that each user gets a consistent view of the data at the time their transaction started. Reads do not block other reads, and concurrent reads never interfere with each other.

8. Observations and Limitations

8.1 What We Observed

- The system maintained zero failures across all 1,000s of stress test requests, demonstrating its robustness under high concurrent load.
- Response times stayed reasonable – the average was around 88 ms for reads and 85 ms for updates, with a worst-case P95 of about 239 ms under 50 concurrent workers.
- Throughput reached 100+ requests per second, which is solid for a single-machine Flask + MySQL setup.
- The RBAC system held perfectly under stress; every single one of the 100 unauthorized update attempts was denied.
- Rollback worked correctly in all three recovery scenarios, at both the API level and the direct database level.

8.2 Limitations

- The system uses last-write-wins for concurrent updates. In a real production system, optimistic locking (version numbers) is used to detect and reject stale writes rather than silently overwriting them.
- Tests were run on a single local machine. In a real distributed deployment, network latency, database connection-pooling limits, and multi-node synchronization would add complexity.
- The concurrent test used only 3 users (one admin, one warden, one student). Real-world workloads would involve hundreds or thousands of simultaneous users.

9. Summary of Results

Script	What It Tests	Verdict	ACID Properties
multi_user_test.py	10 concurrent reads + 100 concurrent updates, no failures	**PASS**	Consistency, Isolation
race_failure_test.py	60 race updates all succeeded legitimately; rollback on forced failure verified	**PASS**	Atomicity, Consistency, Durability
stress_test.py	1000s of requests at 126+ req/s; 100 unauth attempts all blocked; data persisted	**PASS**	Consistency, Isolation, Durability

All four experiments passed. The CallHub system correctly handles concurrent usage, race conditions, failures, and recovery. It maintains ACID properties under both normal and extreme conditions.

10. Team Members and Contributions

Name	Roll Number	Specific Contributions
Anuja Chaudhari	23110034	Done the Testing part for Module A and verified the testing of Module B
Arpita Kumawat	23110045	Done the Testing part for Module B and verified the testing of Module A
